This report has been reviewed by the Eustis Directorate, U. S. Army Air Mobility Research and Development Laboratory, and is considered to be technically sound. The purpose of this investigation was to visually record and study the main and tail rotor vortex patterns in and out of ground effect while varying parameters such as wind azimuth and velocity, main rotor disc loading, jet engine exhaust, and tail rotor location (pusher or tractor).

The investigation was conducted under the technical management of Mr. William Sickles, Mr. John Shipley, Mr. William Yeager, and Mr. Patrick Cancro of the Aeromechanics Division of this Directorate.

ABSTRACT

Water tunnel studies of a model helicopter which entailed a visualization of the main and tail rotor wakes, the inflow patterns, and their subsequent interactions as the wind velocity and wind heading were changed resulted in a significant gain in knowledge ultimately applicable to directional control of helicopters. Of significant interest was the impingement of the main rotor wake with a ground plane, its subsequent spreading outward in a radial manner, and the roll-up of the wake into a standing vortex at the outer edge of this radial expansion of the wake. The position of the rolled-up vortex on the ground plane, with reference to the flow field in and about the tail rotor, plays a dominant role in determining the resultant velocity vectors relative to the tail rotor blades (and consequently the tail rotor's thrust and torque characteristics). The ingestion of the tail rotor wake by the main rotor and the annulus nature of the tail rotor wake are factors which perhaps deserve more attention, in terms of understanding helicopter directional control, than they have received in the past.

FOREWORD

This program was sponsored by the Eustis Directorate, U. S. Army Air Mobility Research and Development Laboratory under Contracts DAAJ02-68-C-0069 and DAAJ02-68-C-0103, Tasks 1F162204A14232 and 1F162204A14231. Messrs. William Sickles, John Shipley, William Yeager, and Patrick Cancro were Project Engineers during some phase of the contracts. Appreciation is expressed to all of these individuals and the agency for their interest in this area.

INTRODUCTION

The inability to reasonably predict, understand, or alleviate tail-rotor/tail-boom/main-rotor influence on performance has resulted in helicopters with inadequate or marginal directional control. In an attempt to better understand the phenomenon involved, a program involving model studies in a water tunnel was performed since water tunnel test procedures offered certain advantages over conventional wind tunnel test procedures. In particular, water tunnel testing permits simultaneous observation of the tip vortex trails associated with both the main and tail rotors and an observation of the inflow streampaths to either rotor. Also, the differences in the kinematic and dynamic viscosities between water and air offer additional advantages for the use of water when scale models are being tested. These advantages will be discussed in detail in later sections of this report.

The general objective of the program concerned a visualization of main and tail rotor tip vortex patterns in and out of ground effect and the inflow streampaths to the tail rotor. More specifically, wind azimuth and velocity, main rotor disc loading, jet engine exhaust, and tail rotor location, i.e., pusher or tractor configuration, were parameters subject to variation. Each of the test configurations was observed visually and documented with high-speed movies and still photography.

TECHNICAL APPROACH TO THE PROBLEM

In establishing the test program there were two major considerations requiring close attention. The first involved a determination that the proposed tests simulated, in a reasonable manner, conditions existing in the operational environment of the full-scale prototype. The second consideration involved the techniques which permitted an observation of the rotors' tip vortex trails (or their wakes) and the streampath inflow patterns.

Discussion of the second consideration may be disposed of in a somewhat less involved manner than the first; therefore, that discussion will be presented first, although in practice, a determination of the scaling factors is the primary consideration because the test results are of dubious value if appropriate scaling is not achieved.

OBSERVATION OF FLOW PATTERNS

The flow patterns or wakes created by an object in incompressible airflows will also be created by the object if water rather than air is the test medium. If observations of vortex patterns are of interest, water as the test medium has a preference to air since air bubbles bled into the vortex region will be centrifuged to the center or core of the vortex. This occurs because of the lesser density of the air bubbles in comparison to the density of water and the rotational motion of the fluid in the vortex. In this manner, the core of the vortex is made easily visible and the location of the core can be documented with regular or high-speed movies, or with still photography.

The air bubbles which depict the core of the vortex cannot distort the core location since the air bubbles can exert no influence on the physical phenomenon which produced the vortex. Also, the bubbles cannot depict a "false core" location since, upon leaving the vortex core or center, the bubbles become widely disbursed through the fluid rotating about the vortex core. Thus the bubbles no longer indicate any well defined or easily discernible core path. Because of this latter characteristic, the amount of air bled into the vortex is somewhat critical if observations of the vortex flow are not to be "muddied" by many free air bubbles in the surrounding field of observation.

The use of the air bubble technique to define the location of vortex cores in water tunnel studies has an advantage over the use of neutral density dye injection (which compares

to smoke injection in wind tunnel investigations) because air bubble injection need only take place near the vortex formation as the lesser density of the air bubbles, coupled with the rotation of the vortex, centrifuges the air to the center of the vortex. In contrast, dye streaks can follow the streampath only from the point of dye injection, and if the dye injection point is not located on the stream-path which eventually enters into the vortex core, the dye streak cannot locate the vortex core; it can only depict some element of fluid in the overall vorticity field.

Neutral density dye streak techniques are of value in water tunnel studies just as smoke techniques are of value in wind tunnel studies when inflow patterns are of interest. Therefore, this study employed the air bubble technique for a determination of the tip vortex patterns and the neutral density dye injection technique for the observation of inflow patterns. In the photographs which illustrate the tip vortex and inflow patterns an arrow indicates the free stream velocity direction.

MODEL/FULL-SCALE SIMILITUDE

In order for test results involving reduced scale models to be of value, certain parameters must be scaled in accordance with established dimensional analysis procedures. In this study it was believed that four characteristics had to be appropriately scaled: model geometry, main rotor lift, jet engine exhaust, and a new characteristic, believed to be important in tunnel studies of models having sharply deflected wakes, identified here as the wake energy dissipation pattern and discussed in a section on page 6.

Model Geometry

Geometric similarity was achieved by a linear scaling of the prototype dimensions. The prototype was the Bell AH-1G (Cobra). The airfoil profile, twist and precone angle of the model main and tail rotors duplicated the prototype exactly. The model rotors were rigid; thus dynamic (mass distribution and rotor attachment) similarity with the prototype rotor was not achieved. However, since this study involved total rotor lift and the interaction of the tip vortex wake patterns of the main and tail rotor, it was believed that complete dynamic similarity was not necessary. It is recognized that with investigations involving main rotor lift fluctuations as a function of rotor azimuth position, rotor blade slap, or similar phenomena, dynamic similarity may become a required scaling

factor.

Rotor Lift

The attainment of appropriate rotor lift similarity involves consideration of the Reynolds number, the incompressible-compressible data correction, and the rotor advance ratio.

Reynolds Number Effect

The degree of matching of the model and full-scale Reynolds number is always of concern, particularly so when testing lifting models. This concern is related to the fact that while the basic slope of the lift coefficient-section attack angle curve may not be significantly altered with a change in Reynolds number, the maximum lift coefficient which can be obtained before the initiation of stall is strongly dependent on Reynolds number.

The prototype Reynolds number, derived from the rotor chord length and for a tip velocity of 800 feet per second, is of the order of 10.3×10^6 . For the water tunnel tests, while the model rotor is quite small, the difference in the kinematic viscosity between air and water is advantageous, resulting in a model Reynolds number of the order of 1.7×10^5 . Thus, there is a difference in the magnitude of the full-scale and model Reynolds numbers. However, the matter of concern when the lift and wake characteristics of a rotor are of interest lies primarily in the maximum lift coefficient obtainable (as a function of radial location) before stall occurs. In the case of rotor studies, the section angle of attack and Reynolds number at different radial stations must be examined to determine the difference in lift characteristics existing at specific radial stations of a rotor when operating at two different Reynolds numbers (model and full-scale).

In Appendix I, such a comparison calculation is made for a rotor operating at Reynolds numbers comparable to the full-scale and model values of this study. That comparison shows that on the basis just described, the calculated difference in the rotor loading at two Reynolds numbers is of the order of 1 percent (for the hover case) at a prototype rotor collective pitch angle corresponding to a load of 8,000 pounds. In other words, the calculated lift performance of a rotor operating at the full-scale and the model Reynolds numbers is

remarkably close when considering only Reynolds number influence.

Compressible Vs. Incompressible Test Data

The full-scale rotor was assumed to have a constant tip velocity of 800 feet per second; thus compressibility effects will influence its performance. On the other hand, the model rotor is operating in water; therefore, its operating regime is fully incompressible. A reasonable approximation for estimating the compressibility effects on incompressible data (when the lifting surface is not in a stall condition) is to employ the Prandtl-Glauert factor, which is $\sqrt{1-M_\infty^2}$. Payne, in Reference 1, shows that the thrust coefficient obtained with an incompressible (nonstalling flow situation, divided by the Prandtl-Glauert factor, provides good agreement with compressible flow thrust coefficient data. The Mach number (M) is taken as that occurring at the 0.7 radial section of the rotor.

Rotor Advance Ratio

To insure appropriate scaling of rotor operation with forward velocity, the advance ratio (μ), defined as the free-stream velocity divided by the rotor tip speed velocity, was determined from full-scale operational values. It was then employed to determine the free-stream velocity required in the tunnel for a constant model main rotor tip speed of 29.31 feet per second.

Jet Engine Exhaust

One aspect of this program concerned the influence of jet engine exhaust on the tail rotor wake. Therefore, a valid scaling of the prototype jet engine exhaust was necessary. In the model, the jet engine exhaust was simulated by a water jet since water was the test medium representing the air in prototype operation. Several different factors for exhaust scaling were developed, and these scaling factors resulted in remarkably close agreement with each other when used to determine the model jet exhaust velocity. Appendix II presents details of the scaling factor selected for use in this study. This factor kept, as a constant, the ratio of the jet engine exhaust momentum to the tail rotor thrust; i.e.,

$$\frac{\text{Total momentum of the jet engine exhaust}}{\text{Tail rotor thrust}} = \text{Constant}$$

Wake Energy Dissipation Pattern

Reference 2 concerned the initial studies of a model helicopter rotor in a water tunnel. That study involved a 12-inch-diameter model of a 48-foot-diameter Bell HU-1D rotor. The same geometric scaling factors described in this report were employed in the construction of that rotor. The tests were performed in a 20-inch by 20-inch cross-sectional test section. The excellent agreement between model lift coefficient-rotor collective pitch angle data when compared with the full-scale values was difficult to understand in view of the theoretical studies of References 3, 4, and 5 and the wind tunnel studies of References 6 and 7, which indicated that relatively large test sections are required if sharply deflected wakes are being investigated. Therefore, in an effort to determine the cause for this apparent variation in water and wind tunnel test section size requirements when studying sharply deflected wakes, a study of the effect of tunnel test section size on rotor lift and wake characteristics when water was the test medium was performed.

That study, Reference 8, revealed that because a real fluid is involved, both the kinematic viscosity of the fluid (which is associated with the Reynolds number) and the dynamic viscosity of the fluid (which is a measure of the shear stress or energy absorption characteristic of the fluid) must be considered if appropriate wake scaling is to be achieved between the model and prototype.

The situation can be considered as one wherein the rotor is injecting energy into the fluid stream, which is then being absorbed by the viscous action of the surrounding fluid. It is believed that the wake energy dissipation pattern, created by the model in the model test medium, must scale the wake energy dissipation pattern created by the full-scale vehicle when in its operating medium if similar wake patterns are to be achieved. From this it follows that when considering tunnel test section size influence on the rotor performance, rotor lift coefficient agreement is not sufficient. The absolute rotor load and the viscosity of the fluid in which the rotor operates should be considered. The importance of the absolute load when testing aircraft models with sharply deflected wakes was recognized by South in Reference 9 but was not carried to the conclusion of including the equally important aspect of fluid viscosity, probably because wind tunnel studies do not entail significant differences in the model test fluid viscosity compared with the viscosity in which the prototype operates. Thus this inability to vary the model

test fluid viscosity may be considered a disadvantage when considering the proper scaling of model studies performed in air with model studies performed in a more viscous fluid such as water.

As an example of the importance of scaling the wake energy dissipation pattern, consider a full-scale hovering rotor operating in air with a rotor disc load of 4 pounds per square foot. Under these conditions, the wake will be projected away from the rotor tip path plane some finite distance. As a first approximation, the distance the wake will be projected away from the rotor tip path plane is solely a function of the rotor disc load per unit area, not the absolute size of the rotor disc area, just as the projection distance of a jet from a nozzle is a function of nozzle pressure and not the absolute nozzle size. From this it follows that if the wake projection distance of a full-scale helicopter rotor (in hover) is defined as that clearance distance above the ground associated with out-of-ground-effect operation, the same clearance distance will be required in the model tests if the same rotor load per unit area is involved. From this it can be concluded that wind tunnel studies of rotors in the hover and transitional flight regimes will require large test sections because appropriate scaling of the Reynolds number will result in rotor disc loadings per unit area approaching those of the full-scale rotor and, as a consequence, the necessary large clearance distances before the presence of a boundary (floor, walls or ceiling) can be tolerated.

The wake energy dissipation pattern is directly related to the viscosity of the fluid in which the rotor is operating and the load per unit area of the rotor disc. If both the model and prototype rotors operate in the same medium, i.e., air, the wake dissipation pattern (or the wake projection distance) will be identical (as a first approximation) if the rotor load per unit area is the same for both the model and the full-scale vehicle. It has already been pointed out that appropriate Reynolds number scaling must be maintained between the model and the full-scale prototype, and it is this requirement which limits the degree of reduction that can be tolerated in the absolute rotor load per unit area when performing reduced scale model investigations.

To further illustrate the importance of maintaining wake energy dissipation similitude, consider the operation of a HU-1D helicopter in hover. Data for this aircraft indicates that it is out of ground effect at a clearance distance of the order of one rotor diameter or about 52 feet. From the preceding discussion, it follows that the

out-of-ground-effect distance will be affected by the viscosity of the fluid as well as by the rotor load per unit area. Considering a reduced scale model study of this aircraft with a ground plane only, it again follows, as a first approximation, that if the reduced scale model rotor load per unit area were the same as for the full-scale rotor, the ground clearance distance would also be 52 feet. In other words, if a 1/4 scale model were being tested with the same rotor load per unit area as the prototype, the data would indicate a clearance of 52 feet. This is a scaling ratio of clearance height to rotor diameter of approximately 4 rather than the correct scaling ratio of approximately 1. It is this inability to properly match the wake characteristics in reduced scale model rotor studies performed in air, while maintaining appropriate Reynolds number scaling, that has led to the correct conclusion by investigators of sharply deflected wakes that relatively large wind tunnel test sections are required.

The matching of the model wake energy dissipation pattern with the prototype was accomplished in these water tunnel studies in the following manner. In Reference 8 a discussion is presented of how the model rotor of a helicopter was tested in the hover mode in the tunnel as a propeller, i.e., the axis of rotor rotation coincided with the longitudinal axis of the test section. Through this approach, it was possible to determine the absolute projection distance of the wake when the rotor was operating at a rotational speed sufficient to insure appropriate Reynolds number scaling. With this operational condition, the wake projected from the tip path plane a distance of approximately 1 model rotor diameter. Therefore, the placement of a boundary at this location should not influence the wake pattern, as no motion of the flow field existed. The wake projection distance was determined by placing tufts on fine cords which spanned the test section on the vertical centerline. The movement of the tufts indicated how far the wake energy projected into the fluid stream before its axial motion was absorbed by the water.

With a tunnel test section size of 28 inches by 28 inches and a rotor diameter of 14 inches, it was therefore possible to satisfy this clearance distance requirement of one rotor diameter by mounting the rotor in the center of the test section. References 3, 4, and 5 have indicated that the presence of the floor dominates the influence of tunnel test section size on rotor performance. Therefore, it follows that if a rotor positioned in the center of an equal-sided tunnel maintains a clearance above the floor such that the floor does not influence the rotor's performance, it is reasonable to expect that the walls and

ceiling will not significantly influence rotor performance either. Details of the testing procedures developed for water tunnel studies of sharply deflected wakes are fully described in Reference 8.

MODEL-TUNNEL SIZE CONSIDERATION

The selection of the model rotor size for the tunnel test section size available, i.e., an equal-sided 28-inch by 28-inch test section, was initially determined through the procedures described above and in Reference 8, wherein it was determined that scaling of the wake energy dissipation pattern was satisfied. In this section it is sufficient to repeat that the model rotor diameter was 14 inches and that for the out-of-ground-effect studies the model was mounted at the vertical center of the test section, thus satisfying the clearance determined earlier. For the ground effect studies, a false floor was installed beneath the model to give the appropriate clearance.

TEST FACILITIES AND EQUIPMENT

TUNNEL

The tests were run in the Oceanics water tunnel. This tunnel is a recirculating, closed-jet-type tunnel having both the water velocity and the test section static pressure as controllable variables. The cross section of the basic test section is equal sided with a side dimension of 28 inches. The section has corner fillets with a 2.36-inch radius. The useable length of the test section is approximately 12 feet. Viewing windows are on all four sides of the test section, thus permitting excellent observation of the model undergoing tests. For this study, the out-of-ground-effect conditions were examined in the basic section. For the in-ground-effect studies, a Plexiglas panel was inserted into the basic section. This panel spanned the test section and extended the length of the section.

In the settling section, just ahead of the nozzle, there are two honeycombs which improve the flow before the water enters the nozzle and passes into the test section. The upstream honeycomb is an egg-crate type consisting of square elements 1.12 inches on a side and having a length of 7 inches. The honeycomb nearest the test section is also an egg-crate type with the individual square elements having a side dimension of 0.96 inch and a length of 16 inches.

MODEL

The model of the helicopter was a scaled version of the Bell AH-1G (Cobra). The two-bladed main rotor had a diameter of 14 inches. An NACA 0012 airfoil formed the cross-sectional profile of the model main rotor blades. The main rotor blades had a uniform twist from the root to the tip of 0.454 degree per foot (full-scale value), and the blades were set into the hub with a precone angle of 2 degrees 45 minutes. The chord length of a model main rotor blade was 0.716 inch. The main rotor blades were fitted into a hub which permitted pitch adjustments to each individual blade. This method of blade-hub attachment does not duplicate the prototype. As pointed out earlier, since the model attachment is rigid, the blades are not permitted to translate except for deflections due to bending loads introduced during operation.

The tail rotor blades were also geometrically scaled versions of the prototype blades. But here also the blades were

rigidly attached to a hub. The tail rotor had a diameter of 2.784 inches, and the chord length of an individual blade was 0.245 inch. The chord thickness was 0.0294 inch. Because of the small physical size of the tail rotor, a mechanism permitting a change in the pitch of the individual blades in the hub attachment was not practical. Therefore, five tail rotors were fabricated with blades having pitch settings of 11, 13, 15, 17 and 19 degrees. The tail rotor blades were untwisted. Photographs of the main and tail rotors are shown in Figure 1.

The model fuselage was a fairly accurate representation of the prototype, although the landing skids and other minor appendages were not included in the model as it was believed that detailed refinements of this type were not necessary in the model to produce a test configuration which would permit a realistic investigation of the problem under consideration. The main rotor drive shaft was directly connected to a gearbox contained in the fuselage. The tail rotor was driven from this gearbox by a flexible belt containing teeth molded into its surface. These teeth fitted gears forming a part of each tail rotor assembly and the gearbox. In this manner, the tail rotor speed was held to a precise ratio with that of the main rotor. Several views of the model are shown in Figure 2.

The test assembly which supported and powered the model consisted of a variable-speed electric motor, a drive shaft instrumented to permit lift measurements when the model was not attached to it, a pylon surrounding the drive shaft, and two support struts for the aft of the model. The entire assembly was fastened to a turntable located in the tunnel floor. In this manner changes could be made in model azimuth. The motor and drive shaft could be tilted both fore and aft and in the lateral direction. An overall view of the test arrangement outside of the tunnel is shown in Figure 3.

The lift of the rotor was sensed in the direction along the drive shaft by utilizing a balance inserted (as a coupling) between the motor and the drive shaft. The balance was calibrated using a rig which incorporated dead weights certified to National Bureau of Standards Tolerance Class C. The calibration was performed with the test assembly mounted in the tunnel, submerged in water, and with the drive shaft operating at the test rotational speed. In this manner, any influence of the bearings in the pylon support was accounted for during the calibration procedure. The output from the balance transducer assembly was fed into an X-Y plotter, permitting the pen deflection, as measured from the trace of the X-Y plot, to be associated with known weights. Calibration was performed before beginning each day's tests.

TEST PROCEDURES

The initial phase of this study involved a determination of the collective pitch setting on the main rotor which would produce the desired (scaled) vertical lifts. This information was obtained through a series of tests with the (isolated) main rotor. A range of collective pitch settings was tested while the equivalent velocity was varied over the speed range from hover to 30 knots. This model lift data was obtained with longitudinal mast angles associated with the 6,000- and 8,000-pound vertical lift conditions of the full-scale vehicle and in conjunction with lateral mast angles of 1.3 and 2.75 degrees. The mast angle data employed in this study are presented in Tables I and II.

The measured model rotor lift values converted to equivalent full-scale values corresponding to full-scale operating conditions of 6,000-foot altitude with an air temperature of 90 degrees Fahrenheit are shown in Figure 4. These data curves were then used in selecting the model main rotor collective pitch values for each of the specified test conditions. The tail rotor collective pitch angles for each test condition were determined from the data presented in Tables III and IV. The obtaining of the proper simulated jet exhaust flow rates was established by performing a series of time-volume measurements for the model (water) jet exhaust as a function of feed water metering valve position.

Having now established all characteristic variables required for the different test conditions, each particular test situation was established in the tunnel and the wake and/or inflow patterns were documented through high-speed movies and still photography. Air was emitted from the tips of both main rotor blades when the tip vortex trail from the main rotor was the subject of interest. However, air was emitted from the tip of only one tail rotor blade since air emitted from both tips produced a tip vortex pattern which tended to "smear" the individual vortex trails together because of the small spacing between successive vortex trails.

TABLE I. LONGITUDINAL MAST TILT ANGLES (DEG)*					
Weight (lb)	Velocity (kt)				
	0	10	15	20	30
9500	-0.3	-0.4	-0.5	-0.6	-0.8
8000	-1.5	-1.7	-1.85	-2.0	-2.3
6000	-0.3	-0.4	-0.5	-0.6	-0.8
Linear interpolations between points are permitted. *USAAVLABS data obtained from full-scale vehicle operational information.					

TABLE II. LATERAL MAST TILT ANGLES (DEG)*		
Weight (lb)	Tail Rotor Pitch Settings (deg)	
	11	19
9500	1.10	2.32
8000	1.29	2.75
6000	1.72	3.69
Linear interpolations between points are permitted. *USAAVLABS data obtained from full-scale vehicle operational information.		

TABLE III. TAIL ROTOR PITCH SETTING, MAXIMUM AND MEAN ANGLE, PUSHER TAIL ROTOR CONFIGURATION, 8000 POUNDS GROSS WEIGHT*

Wind Direction (deg)	Wind Velocity (kt)				
	0	10	15	20	30
0	11	13/13	17/17	17/17	19/17
45	11	14/13	16.3/15.6	16.2/15.7	13.7/15.8
90	11	14.8/13.1	15.8/14.2	15.4/14.15	15/15
135	13	15.9/13.1	13.7/12.5	13.5/12.8	15/15
165	13	16.7/13/25	12.3/11.3	12.3/11.5	13/13
180	15	17/13.25	13/10.9	11.7/11.15	12.5/11
195	15	19/16.2	15/10.4	11.4/10.3	12/11
210	17	19/15.1	17/13.6	12.2/10.45	12/11
225	15	19/14.1	15/9.3	11/8.25	11/11

TEST RESULTS - EVALUATION AND DISCUSSION

The data from this series of investigations consist of high-speed movie clips and still camera photographs. All of these data are at USAAVLABS.

Before discussing and evaluating the observations made during the test program, the conditions and assumptions employed in the test program will once again be reviewed.

1. Geometric similarity of rotor blade shape and fuselage outline was achieved by direct linear scaling.
2. Dynamic similarity of the rotor blade(s) was not achieved since it is believed that a study of the type discussed here does not require such detailed representation between the model and the prototype.
3. The physical size of the model main rotor and the test rotational speed was determined by comparing the calculated rotor lift (at hover) at the prototype and resulting model Reynolds number values and selecting the model size and model rotational speed corresponding to the calculated rotor lifts of a rotor operating at full-scale and model Reynolds number values differing by less than 2 percent.
4. The location of the model rotor in the test section was established as valid by matching the distance between the rotor and the floor with the wake energy dissipation pattern projection distance obtained at hover, when operating at the test speed obtained in 3 above.
5. The model main rotor collective pitch angles employed in this study were established through tests of the model rotor when operating as an isolated unit in the water tunnel. Corrections of these incompressible lift values to compressible values were made through the use of the Prandtl-Glauert factor by assuming a full-scale rotor tip speed of 800 feet per second and the Mach number existing at the 0.7 radial section of the full-scale main rotor blade.

6. The mast and fuselage orientation of the model was established by considering contributions from fore-and-aft cyclic, lateral cyclic, fuselage orientation, and the mast tilt of the prototype vehicle under operating conditions represented in the model test program.
7. Model jet engine exhaust similitude was established by maintaining, as a constant value, the total momentum of the jet engine exhaust divided by the tail rotor thrust, including corrections for density changes in the prototype jet engine exhaust.
8. The same ratio between prototype rotor tip speed and vehicle forward velocity was maintained in the model tests utilizing the model rotor tip speed which resulted in adequate Reynolds number scaling.

The flow field resulting from main-rotor/tail-rotor/tail-boom interaction on VTOL vehicles as the wind heading and velocity change is one of the most complex flow fields produced by any aircraft. Because of its complexity, perhaps a better insight into the ultimate flow situation can be gained if the individual components forming the ultimate flow field are initially reviewed by themselves. The major contributors to the flow field subject to individual review in this section are identified as follows:

1. Variations in the tail rotor inflow and wake as the wind heading and velocity are changed.
2. Interaction of the tail rotor inflow and wake with main rotor inflow and wake as the wind heading and velocity are changed.
3. Effect of the tail boom and tail fin on tail rotor inflow and wake, and possible changes in tail boom drag as the wind heading and velocity are changed.
4. Effect of a ground plane on the above three situations.

Before reviewing each of the above situations, the form of both rotor wakes will be briefly characterized. The blades of the main rotor are uniformly twisted from the root to the tip of the blade, with the higher relative attack angle at the root section. This change in section attack angle

of the blade, as a function of radial location, helps to compensate for the variation in local section lift resulting from the fact that the section rotational velocity component is a function of the radial location. By twisting the blade, the spanwise circulation distribution of the main rotor is controlled so as to obtain as much lift along the span as possible without encountering local stall.

On the other hand, the blades of the tail rotor are not twisted; therefore, the circulation distribution of the tail rotor, ignoring the tip loss effect, is uniformly increasing toward the tip. On the basis of strip theory analysis, the outer 20 percent of the tail rotor blade produces on the order of 65 percent of the total lift (or thrust) of the tail rotor. As a consequence, the majority of the momentum in the tail rotor wake is concentrated in the outer radii locations of the tail rotor disc. Thus the wake of the tail rotor can be characterized as possessing an annular "jet" form rather than a uniform "jet" form. The annulus nature of the tail rotor wake is believed to be a strong contributory factor in the tail rotor wake's response to the presence of the wind and/or the wake of the main rotor.

In the sections which follow, the comments have been arrived at through deduction augmented by knowledge gained from this and previous studies involving rotor wakes. Later sections will deal with specific test observations.

VARIATIONS IN THE TAIL ROTOR INFLOW AND WAKE AS THE WIND HEADING AND VELOCITY ARE CHANGED

In analyzing this flow situation, consider an overhead view of an isolated tail rotor, and mentally visualize the stream-path flow patterns created by operating the tail rotor. This situation will be identified in further discussion as the basic flow pattern. The action of the wind on the basic flow situation can be treated as a uniform Δ -velocity superimposed upon the streampath patterns visualized for the basic flow situation. It follows, therefore, that with a wind heading of 90 degrees, that is, the wind impinging (perpendicular) into the tail rotor disc, the Δ -velocity component associated with the wind reduces the effective pitch setting of the rotor blade's airfoil sections. For this flow situation, an additional increment in the geometric pitch setting of the tail rotor blade is required to produce the same thrust as that which existed before the wind was introduced. It is interesting to observe that the torque requirement related to the thrust produced should not be changed for this wind heading situation. The limiting factor

for this situation is related to the maximum geometric pitch setting to which the tail rotor can be set.

Consider now the situation wherein the wind is at a heading of 270 degrees. The superposition of the Δ -velocity component associated with the wind on the basic flow situation results in an alteration of both the inflow and wake streampath flow patterns. Recalling that a majority of the tail rotor momentum is concentrated near the tip sections of the tail rotor blade, it follows that the inflow streampaths near the tip of the rotor will be reversed, in direction, 180 degrees in order that flow can enter into the tail rotor disc area. Also, considering the flow on the downstream side of the tail rotor disc, the combination of the impinging wind against the tail rotor wake, coupled with the concentration of wake momentum in the outer locations of the tail rotor disc area, results in an expansion, mushrooming, or bellmouthing of the tail rotor wake such that the outer components of the wake, i.e., those components on its periphery, are influenced by the wind velocity vector so as to be swept past (upstream) the tip path plane of the tail rotor disc. However, upon progressing past the tip path plane, the fluid elements, which just were wake elements, are subject to the inflow demands of the rotor and are reingested by the tail rotor. Thus, under certain wind velocity magnitudes, a torus-like streampath pattern is established in and about the tail rotor tip region wherein the same fluid elements are being continuously reingested and expelled.

With the wind at either a 0 or a 180-degree heading, the combination of the wind Δ -velocity component superimposed on the basic flow pattern situation produces a wake pattern which is identical for both cases. There is a skewing of both the inflow and the wake. Depending upon the magnitude of the wind velocity, the thrust and the torque requirements of the tail rotor will undergo change, the thrust being reduced and the torque being increased as the velocity increases. This occurs because the degree of skew distortion of the inflow and wake is directly related to the wind magnitude, and the inflow distortion is directly related to the thrust and torque characteristics of the rotor.

To summarize this section, then, it should be evident that the wind heading and velocity are not always detrimental to the tail rotor in terms of the torque required to produce a given amount of tail rotor thrust. This comment applies to an isolated tail rotor but holds for cases with or without a ground plane. With the wind at a 90-degree heading, the thrust and torque relationship should not be changed,

although the geometric pitch setting of the tail rotor to produce a given amount of thrust would differ. A deterioration in the amount of tail rotor thrust for a given torque input occurs when the heading of the wind is such as to influence both the inflow and wake. This situation would appear to exist for wind headings from about 190 to 290 degrees. The degree of deterioration in the rotor thrust-torque relationship is dependent upon the absolute wind velocity and the wind heading under consideration.

INTERACTION OF THE TAIL ROTOR INFLOW AND WAKE WITH MAIN ROTOR INFLOW AND WAKE AS THE WIND HEADING AND VELOCITY ARE CHANGED

In this section, the same mental visualization procedures will be employed as in the previous section. However, the mental visualization of the basic flow patterns now requires consideration of both the overhead and the side viewing positions since the flow patterns now under consideration are more complex than the flow situation discussed in the preceding section.

Considering both the tail rotor and the main rotor wake without wind and out of ground effect, decompose the velocity vectors associated with the individual fluid elements comprising each wake into their axial and rotational components. The tail rotor wake intersects or joins with the main rotor wake at right angles, and in this interference region, the rotational component of the main rotor wake is in the opposite direction relative to the axial component of the tail rotor wake. The rotational component of the tail rotor wake (in the interference region) is in the same direction as the axial component of the main rotor wake. Because of the combination of the velocity vectors of the two wakes, the tail rotor is deflected slightly downward and, at the same time, curls around the outer periphery of the main rotor wake.

Reviewing the flow pattern situation with the introduction of wind at a heading of 90 degrees, and continuing the situation of out of ground effect, the combination of the inflow and wake trajectories of fluid elements associated with the main rotor disc region produces a pre-rotation or swirl of the inflow streampaths into the tail rotor. For a pusher tail rotor configuration, this induced pre-rotation of the inflow to the tail rotor coincides with the rotational direction of the tail rotor. As a consequence, it would appear reasonable that, with the main rotor

operating, the required tail rotor pitch setting would be somewhat greater than it would be without the main rotor operating.

Considering the situation with the wind at a heading of 270 degrees, the action of the main rotor inflow and wake with reference to inducing pre-rotation to the inflow to the tail rotor is not quite as pronounced as for the 90-degree wind heading because of the required 180-degree turning of the flow as it enters the tail rotor disc. However, for this situation, the rotational component of the main rotor wake enhances the wind velocity vector and in doing so augments the tendency for the tail rotor wake to be blown back and reingested.

It will be recalled that with wind headings of 0 or 180 degrees, the inflow and wake patterns of an isolated rotor duplicated each other. With the main rotor operating, the situation changes significantly. With the wind at a 0-degree heading, the inflow to the tail rotor is under the direct influence of the main rotor wake, which, at the higher wind velocities, is transported back and into the tail rotor, particularly in the region associated with the lower half of the tail rotor disc. This flow situation also introduces pre-rotation of the flow into the tail rotor disc, but the major significance appears to be related to the difference in the inflow to the lower half of the tail rotor disc area which is under the influence of the main wake, compared with the inflow to the upper half of the tail rotor disc which is not.

With the wind at a 180-degree heading, the main rotor wake is blown away or downstream from the tail rotor; thus its influence on tail rotor performance at the higher wind velocities is negligible. At velocities, above the order of 15 knots, the tail rotor inflow approaches conditions similar to that of an isolated tail rotor.

The flow situations just reviewed were those wherein a ground plane was not present. With the insertion of a ground plane, significant changes occur in the inflow and wake pattern of both the main and tail rotors. The major cause of these changes is the main rotor wake, which upon impingement with the ground plane spreads outward and then rolls up in a process reminiscent of a standing vortex. For the hover condition, the standing vortex can be characterized as a ring vortex. With the introduction of wind, this standing ring vortex degenerates into a horseshoe-shaped vortex with the open end of the horseshoe downstream. At wind velocities of the order of 20-25 knots, the angle of impingement of the main rotor wake with

the ground plane is such that no roll-up of the wake occurs on the upstream side, i.e., the closed end of the horseshoe, although there is some impingement and roll-up of the wake along the ground plane parallel with the direction of the wind, i.e., the open end of the horseshoe. At wind velocities above the order of 25-35 knots, the main rotor wake no longer impinges on the ground plane in the region beneath the main rotor. The absolute wind velocity at which this impingement ceases is dependent on the main rotor lift value.

Turning now to a review of the tail rotor region flow conditions with wind, consider first the situation with the wind at a heading of 90 degrees. The influence of the main rotor wake and its formation into a rolled-up vortex on the ground plane is of concern at wind velocities from about 10-25 knots. Above 25 knots, the impingement of the main rotor wake against the ground plane occurs downstream of the tail rotor location, and therefore it no longer influences the flow patterns associated with the tail rotor inflow. However, the inflow of the main rotor influences the inflow to the tail rotor over the entire wind velocity range examined. As mentioned before, the nature of the inflow to the main rotor is such as to produce a pre-rotation of the flow entering the tail rotor disc area. In addition, the wind has the effect of "stretching" the tail rotor (downstream) before it mixes with the main rotor wake and inflow.

At a 270-degree wind heading, the reflection of the main rotor wake from the ground plane again influences both the inflow and wake pattern to the tail rotor for velocities from about 10-25 knots. As with the wind at a 90-degree heading, above 25 knots, the impingement of the main rotor wake with the ground plane also occurs downstream such that it no longer has an influence on the inflow to the tail rotor. The wind at this heading has a particularly strong influence on the wake of the tail rotor in that, as the velocity increases, the wind causes the tail rotor wake to blow back upon itself and in this manner becomes reingested. In blowing back, some of the tail rotor wake is also ingested by the main rotor.

Test conditions with the wind at a 180-degree heading, and covering a sector of the order of 45 degrees to either side of the 180-degree azimuth, afford the most interesting observations of main rotor wake impingement with the ground plane and its resulting influence on the tail rotor inflow and wake patterns. As mentioned earlier, the main rotor wake impinges against the ground plane and spreads radially outward, ultimately rolling up into a standing vortex, which at hover is a ring vortex. With the wind at the 180-degree heading, the position of this rolled-up or standing vortex

is shifted from a position upstream and away from the inflow region of the tail rotor to locations closer and closer to the tail rotor as the wind increases. At wind velocities of the order of 10 knots, the position of the standing vortex on the ground plane is just upstream of the tail rotor. At winds of the order of 12-13 knots, the position of this standing vortex is such that it appears to produce the maximum influence on both the inflow and wake characteristics of the tail rotor. At a velocity of the order of 15 knots, the rolled-up vortex is formed downstream of the tail rotor location, and thus its influence declines.

The critical situations can therefore be characterized as existing for wind velocities of the order of 10-15 knots and wind headings of the order of 120-250 degrees. Over this sector of wind headings, the presence of the rolled-up vortex on the ground plane can and does significantly influence the tail rotor inflow and wake by forming in the immediate vicinity of the tail rotor. At a wind heading of 180 degrees, it appears that the maximum influence should occur for winds of the order of 12-13 knots, while a wind heading of 225 degrees probably produces maximum influence at a wind velocity closer to 15 knots. The powerful influence of the standing vortex formed on the ground plane appears to be associated with the combination of its rotational velocity vectors in conjunction with the axial velocity vectors of the main rotor wake and the rotational direction of the tail rotor. Because of the manner in which these individual velocity vectors unite, the resultant velocity vector approaching the tail rotor blades is drastically altered as the standing vortex passes from a location directly upstream to one directly downstream of the tail rotor inflow region.

With the wind at a 0-degree heading, the inflow and wake patterns of the tail rotor with a ground plane are very similar to those without a ground plane. For example, at a zero wind velocity, the standing vortex created by impingement of the main rotor wake with the ground plane occurs well downstream and outside of the range wherein it can influence the inflow or the wake of the tail rotor. Thus this situation with a ground plane is similar to that without a ground plane. As the velocity increases, that portion of the standing vortex originally nearest the tail rotor location is projected further downstream and rapidly ceases to exist as that portion of the standing vortex becomes the open end of the horseshoe shape. The closed portion of the horseshoe shape formed by the standing vortex never approaches the tail rotor disc area since impingement and roll-up of the wake with the ground plane no longer occur when the velocities exceed the order of 20-25 knots, and wind

velocities higher than this are required to deflect the main rotor wake so that impingement occurs in the tail rotor region.

EFFECT OF THE TAIL BOOM AND TAIL FIN ON TAIL ROTOR INFLOW AND WAKE, AND POSSIBLE CHANGES IN TAIL BOOM DRAG AS THE WIND HEADING AND VELOCITY ARE CHANGED

In turning our attention to the influence of the tail boom and tail fin on directional control, the effect of the wind on the tail boom and its effect on the tail fin will be examined separately. With the exception of winds centered about and in the general region of headings of 180 degrees, the tail boom is always submerged in the main rotor wake, at least to wind velocities of the order of 25 knots. The rotational component of the main rotor wake always impinges on the port side of the boom; thus this rotational component of the main rotor wake coupled with the corresponding low pressure on the downstream side of the tail boom always produces a force which augments the tail rotor thrust in maintaining directional control. Wind headings of 0 and 180 degrees introduce no force on the boom. The maximum influence of the wind on the boom occurs at a heading of 270 degrees, where it augments the tail rotor thrust, and again at a heading of 90 degrees, where it subtracts from the tail rotor thrust.

The flow about the tail fin is believed to be primarily controlled by the action of the tail rotor itself; thus the influence of the wind on the tail fin (by itself) is believed to be negligible in terms of affecting directional control. The presence or lack of a ground plane is not believed to have any effect on the influence of the wind on the tail boom or tail fin.

ANALYSIS OF THE TAIL ROTOR INFLOW AND WAKE PATTERNS IN CONJUNCTION WITH TAIL ROTOR PITCH SETTINGS FOR PUSHER AND TRACTOR CONFIGURATIONS

If the flow patterns discussed in the preceding sections are now considered in conjunction with the tail rotor pitch settings required during operation of the full-scale vehicle, this additional information may be used to help clarify and interpret the effects of the different variables affecting the flow patterns about the helicopter (model) and thereby also aid in understanding the variations in required tail rotor thrust.

Tables III and IV presented the tail rotor pitch settings

required for both the tractor and pusher configurations of the helicopter studied in model scale during this investigation. This information, obtained from flight data and through USAAVLABS, permits a recognition of some of the difficulties encountered when working with full-scale data. The first inconsistency noted in the tables is the tail rotor pitch setting(s) required for a zero wind velocity as a function of wind direction (heading). It appears that different tail rotor settings are required solely as a function of wind direction. Obviously, if no wind is present, vehicle orientation with reference to the wind is not a definable characteristic. Therefore, the noted differences in the required tail rotor pitch settings with a zero wind velocity are either errors in determining the tail rotor pitch setting or the possibility that some wind did exist, or a combination of these factors.

However, while there is some question as to the accuracy of the tabulated information, it should be possible to deduce qualitative trends from these data which will augment the insight gained from the flow patterns observed during the experimental studies. But before doing so, one other factor should be mentioned when this data is employed in interpreting the influence of the flow patterns on tail rotor thrust performance. That factor is that the main rotor cyclic pitch control is tied in with the tail rotor pitch setting; thus it is impossible to separate the influence of either main rotor cyclic or tail rotor pitch as independent variables.

Consider first the matter of a pusher or tractor tail rotor configuration with a zero wind condition. With no wind present, any difference in the required tail rotor pitch settings should be directly attributable to the tail rotor location relative to the tail fin. Tables III and IV present no clear-cut evidence, but out of the 12 pitch settings listed for the zero wind condition, the pusher configuration lists five 11-degree situations while the tractor configuration always requires pitch settings greater than 11 degrees. Therefore, it appears, on this basis, that the tractor tail rotor configuration requires slightly higher pitch settings than the pusher tail rotor configuration to maintain directional control when no wind is present. This conclusion at least implies that for the condition of unaltered inflow to the tail rotor, i.e., the tractor configuration, less thrust is produced than for the case where the inflow to the tail rotor is subjected to passing about the tail rotor fin prior to entering the tail rotor, i.e., the pusher configuration. However, the fact that the direction of rotation of the tail rotor is changed between tractor or pusher configuration cannot be completely ignored,

particularly when one recognizes how the components of the tail and main rotor inflow and wake interact with each other. However, this indication that the tractor tail rotor configuration seems slightly less effective than the pusher configuration is also augmented by examining all 60 conditions listed in Tables III and IV. Reviewing the information in the tables, it can be determined that the higher pitch setting is required by the tractor configuration in 34 of the cases listed. For 15 of the listed cases, the pusher configuration requires the higher tail rotor pitch setting, and for 11 cases there is no difference. It should be pointed out that no conclusion can be drawn from this information with regard to the tail rotor torque requirements since it is possible that a given tail rotor pitch setting may produce more thrust and consequently require more torque because of changes in the inflow or wake patterns.

The material in Tables III and IV does, however, permit additional substantiation of comments offered earlier. For example, considering the case of a 90-degree wind heading, the higher wind velocities indicate that greater tail rotor pitch settings are required in order to maintain directional control than are required for wind headings of the order of 270 degrees, for both the tractor and pusher configurations. This required difference in tail rotor pitch setting agrees with the earlier discussions of the flow patterns concerning an isolated tail rotor. There it was pointed out that the introduction of wind at a heading of 90 degrees was comparable to an axial Δ -velocity increase in the inflow velocity vector to the tail rotor; thus higher tail rotor pitch settings would be required to produce the same thrust as that produced without the presence of the wind.

It might be of value to examine once more the data contained in Tables III and IV, this time with reference to the maximum tail rotor pitch setting required to maintain directional control. The choice between a pusher or a tractor tail rotor configuration may well be determined by the limiting operating conditions; on this basis, the tractor configuration seems to be the better choice. The pusher tail rotor arrangement requires the maximum geometric tail rotor pitch setting for operation over the wind heading sector of about 195-240 degrees and requires this maximum pitch setting when encountering the relatively low wind velocity of 10 knots. Also, the pusher tail rotor configuration requires the maximum pitch setting with a zero wind heading and a velocity of 30 knots. The tractor tail rotor configuration requires the maximum tail rotor pitch setting with the wind in the heading region of 90 degrees and for velocities above 15 knots. Thus, from an operational standpoint, the tractor

configuration seems preferable, since conditions requiring the maximum tail rotor pitch setting by the pusher arrangement are much more likely to occur than the conditions requiring the maximum tail rotor setting for tractor operation. In other words, operations with a wind velocity of 10 knots and the wind at headings in the sector of 195-240 degrees, or with zero heading and a velocity of 30 knots, are much more likely to occur than operations with a wind heading around 90 degrees and wind velocities above 15 knots.

WAKE OBSERVATIONS, ANALYSIS, AND DISCUSSION

Directional control of a helicopter in the horizontal plane is maintained during flight by balancing the two factors of torque of the main rotor with thrust of the tail rotor. Therefore, any analysis of directional control must, by necessity, include data applicable to both factors. Of course, the tail rotor must balance the torque of the main rotor if directional control is to be achieved, but an understanding of both factors is required if the most effective control system is to be obtained.

Unfortunately, information which permits an examination of the tail rotor pitch setting in conjunction with main rotor cyclic and/or collective pitch settings was not available through USAAVLABS. While that information would not be as desirable in effective interpretation of the inflow and wake observations as data obtained from a controlled study, it would have permitted an additional approach or an alternate method of separating the interaction and subsequent effects of the main and tail rotor inflow and wake in understanding helicopter directional control performance.

Four factors are of major importance in this test program:

1. The importance of the presence or absence of a ground plane, particularly with winds up to 25 knots and covering an azimuth sector of 100 degrees centered about a wind heading of 180 degrees.
2. The interaction of the tail rotor wake with the inflow to the main rotor, the significance of main rotor inflow on tail rotor inflow, and the minimum influence of main rotor wake on tail rotor inflow and wake except when the main rotor wake impinges on the ground plane and is reflected into the tail rotor inflow area.

3. The minor effect that jet engine exhaust has on the wake patterns. (Note: the jet exhaust studies were performed out of ground effect only).
4. The annulus nature of the tail rotor wake which results because of the concentration of wake momentum near the outer periphery of the tail rotor wake, since all radial sections of the tail rotor are at the same pitch setting.

While the above factors are listed in order of their importance, development of a logical presentation of the knowledge gained during this study should perhaps start with the interaction of the main and tail rotor wakes rather than the inflow situations and then proceed from that situation.

When viewed from either the side or the overhead position, the tip vortex trails produced by an isolated main rotor in the hover mode form a concentric helix pattern. This pattern is shown in Figure 5. With the introduction of a uniform stream velocity (simulating wind), the tip vortex trails become skewed, but the basic symmetry of the wake pattern persists. This is shown in Figure 6, where the wake patterns associated with a simulated wind velocity of 35 knots are viewed from both the overhead and the side positions. (Arrows on the photographs show the general wind direction.)

When a complete helicopter model is tested, the interaction of the tail rotor wake with the main rotor inflow and wake is most evident. Figure 7 is an overhead view illustrating how the main rotor tip vortex wake trails are distorted by ingestion of the tail rotor wake by the main rotor. A side observation of tail rotor wake ingestion by the main rotor is shown in Figure 8. The importance of a distortion in the inflow streampaths and the resulting effect on rotor thrust and torque characteristics should not be minimized. The importance of inflow perturbations and their effect on airfoil performance are well known [10, 11]. Also, the influence of inflow velocity perturbations on thrust and torque characteristics has received considerable attention in the marine propulsor field [12, 13]. Therefore, it seems prudent to suggest that the degree of main rotor torque fluctuations resulting from tail rotor wake ingestion is a fruitful field of investigation if a complete understanding of the helicopter directional control problem is desired.

That the action of the main rotor drastically alters the inflow and wake patterns of the tail rotor should come as no surprise, but the degree of distortion is usually considered remarkable when viewed for the first time. Figures 9 through 13 illustrate how the tail rotor wake is altered through

operation of the main rotor. These observations are made from an overhead viewing position for specific wind headings and velocities, both with and without main rotor operation. The tail rotor wake was made visible by bleeding air from one tail rotor tip, and the photographs were taken at the relatively slow exposure time of 1/60 second to permit a streak photograph of the tip vortex trail(s) to be obtained, rather than a photograph wherein the individual tip vortex trails are stopped. All photographs in this series of five figures were taken at the hover condition and with equivalent wind velocities of 15 and 30 knots. There is no ground plane present in any of these figures.

Figure 9 presents views of the tail rotor wakes associated with a wind heading of zero degrees. Of particular interest are Figures 9(a) and 9(d), which show the effect of main rotor operation in hover. Figure 10 presents photographs with a wind heading of 180 degrees, while Figure 11 presents photographs with a wind heading of 230 degrees. Figures 11(c) and 11(f) are for a 30-knot wind condition and offer good observations of the nature of the blowback and re-ingestion of the tail rotor wake by the tail rotor due to the action of the wind both with and without main rotor operation. Figure 12 presents photographs for a wind heading of 250 degrees. In this figure, the 15-knot velocity case, Figure 12(e), offers a good observation of the manner in which the outer periphery of the tail rotor wake is expanded or mushroomed outward by the impingement action of the wind. This expansion of the tail rotor wake, which is believed to result from the fact that the majority of the wake momentum is concentrated in the outer periphery, has been mentioned in earlier discussions. Figure 13 presents photographs for a wind heading of 270 degrees. Figures 13(e) and 13(f) again offer good observations of the blowback and reingestion of the tail rotor wake by the tail rotor. Of course, as mentioned before, the main purpose of this series of figures is to show how the tail rotor wake is altered by operation of the main rotor. Because of the variation in this effect, individual examination of all photographs in the figures is required for a thorough understanding of this interaction.

Several side observations of the tail rotor wake when out of ground effect are shown in Figures 14 and 15. The photographs comprising these figures illustrate the manner which the tail rotor wake is drawn upward and then into the main rotor disc area by the action of the inflow into the main rotor. These figures, in conjunction with the immediately preceding series of photographs, illustrate the manner in which interaction of the tail rotor wake and main rotor inflow can occur.

The series of photographs shown in Figures 16 through 24 illustrates inflow patterns to the tail rotor, how this inflow is affected by main rotor operation in the presence of a ground plane, and how the tail rotor wake interacts with the main rotor inflow under these conditions. As mentioned in earlier discussions, one of the observations of major importance associated with this study concerned the impingement of the main rotor wake with the ground plane, its roll-up into a standing vortex, and how this rolled-up vortex affected the inflow to the tail rotor.

In the absence of wind or hover operation of the main rotor, the streampath inflow to the tail rotor forms the classical "sink" pattern. This pattern is shown in Figure 16. The introduction of a 10-knot wind at a heading of 180 degrees produces inflow patterns as shown in Figure 17 when the model is viewed from the side. The upper photograph in this figure shows the inflow pattern associated with the main rotor not operating while the lower photograph was taken with the main rotor operating. Without main rotor operation at this 10-knot velocity, the classical inflow streampaths to the rotor still occur, but the relatively small disturbance of the lower dye streak clearly indicates the localized extent of tail rotor inflow on the region surrounding the tail rotor location. With main rotor operation, the outer boundary of the main rotor wake roll-up is clearly defined by the presence of the dye. The "eye" of the rolled-up vortex is clear of dye. The portion of the vortex can be seen to be just upstream of the tail rotor. While this photograph may indicate that the flow into the tail rotor is rather badly confused, an overhead view for the same 10-knot condition presented in Figure 18 shows the degree of disturbance. This figure shows the uniform inflow to the tail rotor without main rotor operation and the extent of flow disturbance existing in the tail rotor inflow region when the main rotor is operating.

Increasing the wind velocity to 15 knots and retaining the 180-degree heading produces the inflow patterns shown in Figure 19 for a side viewing position and in Figure 20 for an overhead viewing position. From these figures it can be seen that the roll-up of the vortex formed by main rotor wake impingement on the ground plane no longer influences the inflow to the tail rotor or the tail rotor wake. This is shown particularly well in the overhead viewing position photographs, where the dye streampaths into the tail rotor are clearly undisturbed. The critical wind velocity at the 180-degree heading, in terms of positioning the main rotor rolled-up vortex in the region of the tail rotor so as to produce the maximum change in tail rotor thrust performance, occurs, as was mentioned in earlier discussions, between

12 and 13 knots.

Side viewing position observations indicating how the location of the main rotor wake and its impingement on the ground plane are altered as the wind heading is changed are shown in Figure 21. In this series of photographs, the wind velocity is 15 knots and the wind headings illustrated are for 180, 195, 210, and 225 degrees. From a viewing of these photographs, the inflow patterns might be interpreted as indicating that considerable disturbance exists in the inflow region to the tail rotor. Figure 22, comprised of overhead position photographs of the same conditions, shows that this is not true. The unconfused inflow patterns to the tail rotor with main rotor operation are clearly established, and Figure 23 shows that they do not vary significantly from the inflow patterns existing without main rotor operation.

The combination of main rotor and tail rotor interactions on each other's inflow and wake pattern is perhaps best characterized by viewing the situation with a wind heading of 90 degrees. In Figure 24, conditions with the main rotor operating and not operating are shown for wind velocities of 10, 15, and 25 knots. The left-hand series of photographs presents the inflow and wake patterns associated with the main rotor not operating. These photographs are of particular interest since they illustrate the earlier-mentioned observation that the presence of the wind at a heading of 90 degrees reduces the effective pitch setting of the tail rotor. All of the tests performed in the presence of the ground plane were taken with a single tail rotor pitch setting. Therefore, any change in the inflow or wake patterns cannot be related to changes in tail rotor pitch setting. In producing thrust, the streampaths passing through a rotor or propeller disc area are contracted. From the photograph associated with the 10-knot wind velocity case, Figure 24(a), it is clearly evident that the dye streaks, upon passing through the tail rotor disc area, are rather sharply contracted, thus indicating that thrust is being produced. With a wind velocity of 15 knots, Figure 24(b), the contraction of the dye streaks entering the tail rotor disc area is almost negligible; thus in actual practice, the geometric tail rotor pitch setting would have to be increased over that required at 10 knots to maintain the same amount of tail rotor thrust or the same degree of directional control. (That an increase in the tail rotor pitch setting is necessary with a change in the velocity from 10-15 knots with a wind heading of 90 degrees can be verified by referring to Tables II and III.) At a 25-knot wind condition, Figure 24(c), no contraction of the dye streams entering the tail rotor disc area is evident, indicating that the tail rotor pitch setting would have to be increased once again to produce thrust.

Turning our attention to the configuration with the main rotor operating, the situation for a 10-knot wind velocity, Figure 24(d), shows that the dye streaks approaching the tail rotor disc area are being retarded and prevented from entering the tail rotor disc area. This occurs as a result of the main rotor wake's impingement upon the ground plane and the main rotor wake's outward radial motion. At a wind velocity of 15 knots, Figure 24(e), some of the retardation of the inflow is still evident, but more important is the uplifting of the general inflow upstream of the model and its ingestion into the main rotor disc area. At a wind velocity of 25 knots, Figure 24(f), the lower dye streak clearly establishes the limit of the main rotor wake impingement and roll-up on the ground plane, while the upper dye streaks illustrate how the flow in the tail rotor region is influenced by main rotor inflow demands.

The path of the tail rotor wake as indicated by the air bubble streaks emitted from the tail rotor is also of considerable interest. Observe that in all of the photographs taken without main rotor operation, the tail rotor wake travels horizontal and parallel to the ground plane. With main rotor operation and at a wind velocity of 10 knots, the lower portion of the tail rotor wake interacts with the main rotor wake and thus is distorted in a downward direction toward the ground plane. At a wind velocity of 15 knots, some distortion of the tail rotor wake in the downward direction is still evident, but the influence of the main rotor wake appears to be decreased over the 10-knot case. However, at 25 knots, the wake of the tail rotor is projected in an upward direction. This occurs because the tail rotor wake is now influenced both by that portion of the main rotor wake traveling toward the ground plane and by that portion of the main rotor wake reflected upward after impingement with the ground plane. Under this 25-knot wind condition, the tail rotor wake is more closely aligned with the reflected portion of the wake than with the downward portion of the wake.

JET ENGINE EXHAUST

The studies involving an evaluation of the effect that jet engine exhaust had on the main-rotor/tail-rotor interaction were made for the out-of-ground-effect condition only. Observations with the pusher tail rotor configuration were made both with and without simulated jet engine exhaust. No significant change in either the tail rotor wake or the nature of the interaction of the tail rotor wake with the main rotor wake could be noted for any of the wind velocities or wind headings investigated. It did appear as if the interaction of the main rotor wake with the tail rotor wake

was slightly more pronounced when the jet engine exhaust was being simulated. This seems reasonable in that the velocity component of the jet engine exhaust would tend to distort the main rotor wake; thus the interaction at the interference plane of the tail rotor wake with the main rotor wake should be accentuated.

While no significant change could be noted in the tail-rotor interaction, in being completely objective it must be recognized that in actual operation, in addition to the jet velocity flow stream which was scaled in the model studies, the local air density changes during full-scale operation because of the higher temperature of the jet engine exhaust. This local change in air density could well influence the local thrust (and consequently torque) performance of both the main and tail rotors. Whether this occurs and the magnitude of this influence (if there is any) could not be ascertained in this study. What this study shows is that the velocity components of the jet engine exhaust do not influence the tail-rotor/main-rotor interaction patterns to any significant degree.

When studying the tractor tail rotor configurations, a series of photographs was taken at different equivalent jet engine exhaust velocities for different wind velocities at a wind heading of 180 degrees. This series of photographs is shown in Figures 25 and 26. Figure 25 presents photographs for the zero wind (hover) condition. The series (a) photographs present the flow patterns associated with jet engine exhaust without the main or tail rotor in operation. These photographs show that at a simulated jet exhaust velocity of 112 feet per second, which is well below the operational exhaust velocity of 226 feet per second, the jet engine exhaust has extended into the tail rotor region. At higher jet velocities, the exhaust projects well beyond the tail rotor region. The series (b) photographs present the same jet engine exhaust velocity conditions but with the main and tail rotors of the model now operating. From these photographs, it can be seen that the downwash from the main rotor deflects the simulated exhaust downward and that this downward deflection of the jet engine exhaust continues to equivalent jet engine exhaust velocities of 290 feet per second, or well above the operational jet exhaust velocity of 226 feet per second. At the equivalent full-scale operating condition of an engine exhaust velocity of 226 feet per second, the outer projection edge of the exhaust stream approaches the tail rotor region and, while it does not enter the tail rotor area, the influence of the main and tail rotor's wakes on the flow in the general area is evident.

In Figure 26, the flow conditions for equivalent wind velocities of 10, 20, and 30 knots at a heading of 180 degrees are shown. The only interaction of the jet engine exhaust with tail rotor flow at the operational jet exhaust velocity of 226 feet per second occurs with a 20-knot wind, and the interaction is with the wake, not the inflow side of the tail rotor.

CONCLUSIONS

In this study, the interactions of the main-rotor/tail-rotor wakes and inflow were examined. This information is of value as input to the directional control problem which exists with certain helicopter designs. The direct observation of the inflows and wakes of both the main and tail rotors has permitted a significant advancement in the knowledge applicable to such flow situations. The major conclusions of this investigation are:

1. The presence of a ground plane is important. With a ground plane, the main rotor wake of a helicopter (at hover) impinges against the ground plane and then spreads radially outward. At the outer periphery of this radial expansion, the wake rolls up into a standing vortex.
2. The introduction of a wind velocity component causes the location of the rolled-up vortex to shift on the ground plane and also changes the rolled-up vortex from one resembling a ring vortex to one which has a horseshoe shape, with the open end of the horseshoe downstream. The impingement and roll-up of the main rotor wake on the ground plane occurs to velocities of the order of 20 knots. Above that velocity, the wake from the main rotor does not impinge on the ground plane in the area directly beneath the rotor such that roll-up occurs.
3. With the introduction of winds covering an azimuth sector of the order of 100 degrees and with this azimuth sector centered above a heading of 180 degrees, it can be understood from 2, above, that the closed portion of the horseshoe-shaped rolled-up vortex will be positioned nearer and nearer the tail rotor as the wind velocity is increased. At some value of wind velocity, and depending upon the wind heading, the rolled-up vortex will be situated such that it has a maximum influence on the flow in and about the tail rotor region. For example, with a wind heading of 180 degrees, it appears as if the maximum influence on the tail rotor thrust should occur with wind velocities of the order of 12-13 knots.
4. Ingestion of the main rotor wake by the tail rotor and the tail rotor wake by the main rotor both

occur under certain wind headings and wind velocities. From these flow observations, it appears as if ingestion of the tail rotor wake by the main rotor would have more influence on helicopter directional control than the reverse case of main rotor wake influence on the tail rotor, except for cases with a ground plane where the main rotor wake impinges, rolls up, and then becomes located in the tail rotor region. The influence of the tail rotor wake on main rotor ingestion and its subsequent influence on directional control, by affecting the torque of the main rotor, is associated with the recognized variation in the thrust and torque performance of lifting surfaces when subjected to inflow perturbations.

5. The annulus nature of the tail rotor wake, that is, the concentration of momentum in the outer periphery of the wake, appears to be a strong contributory factor to the unsteadiness of the tail rotor thrust, particularly when the wind impinges against the tail rotor wake.
6. The jet engine exhaust velocity component, at the operational exhaust velocity, appears to have little influence on the inflow or wake interaction patterns. However, it must be noted that these exhaust studies were taken for the situation of out of ground effect only and that local density differences in the test medium such as occurs under full-scale operation in air were not scaled.
7. Excluding wind headings of the order of 195-240 degrees at wind velocities of 10-15 knots, the inflow and wake of the tractor tail rotor configuration appear to have slightly more interaction with the main rotor wake and inflow than the pusher tail rotor configuration does. Examination of operational data confirms that slightly higher tail rotor pitch settings are required. However, at the wind headings of the order of 195-240 degrees and at wind velocities of 10-15 knots, the pusher tail rotor configuration introduces the more significantly obvious tail-rotor/main-rotor wake and inflow mentioned; the pusher tail rotor configuration possesses the most unsteady tail rotor wake, i.e., the wake seems to pulsate when it is observed

with high-speed photography. Therefore, on the basis of flow observations alone, the tractor tail rotor configuration seems to be a slightly better choice than the pusher tail rotor configuration.

APPENDIX I

COMPARISON OF ROTOR LIFT AT TWO REYNOLDS NUMBERS

The necessity for Reynolds number scaling is a well recognized requirement for the performance of meaningful model studies. Using simple strip theory, it is shown in Table V that the vertical lift developed by a hovering rotor operating at a Reynolds number corresponding to flight conditions differs by less than 2 percent from that produced when the rotor is operating at a Reynolds number corresponding to the present model tests performed in a water tunnel.

The ability to closely match the total rotor lift while operating at two widely different Reynolds numbers lies in the fact that below the stall, blade lifting characteristics are virtually independent of Reynolds number, and Reynolds number serves mainly to limit the maximum lift that can be achieved at any radial section. For a helicopter rotor operating at a full-scale Reynolds number all sections are likely to be operating below the stall, while for operation at model-scale some sections may have stalled out. However, if at model-scale only the inboard sections are stalled, the effect on the overall lift will be small since the inboard sections contribute little to the overall lift whether they are stalled or not. Consequently, if model tests are carried out at Reynolds numbers for which only the inboard sections are stalled, such tests will still give good predictions of full-scale total lift, and that is the situation maintained in the water tunnel investigations.

The situation presented in Table V is for a 44-foot-diameter AH-1G rotor having a chord of 27 inches and an NACA 0012 airfoil. The twist in the rotor blade is 0.454 degree per foot. The collective pitch angle is 13.3 degrees. The tip speed of the rotor is assumed to be a constant 800 feet per second. Incompressible flow has been assumed for this comparison, a valid assumption since the comparison is limited solely to an examination of the influence of Reynolds number on total rotor lift. Compressibility effects are likely to be important for determining the true total rotor lift and in the model studies, the incompressible lift values were adjusted to compressible values through the use of the Prandtl-Glauert factor.

TABLE V. COMPARISON OF CALCULATED TOTAL ROTOR LIFT AT TWO REYNOLDS NUMBERS; HOVER CONDITION; 44-FOOT-DIAMETER ROTOR; 800 FEET PER SECOND TIP SPEED; INCOMPRESSIBLE FLOW ASSUMED; AIR DENSITY OF 0.00218 SLUG PER CUBIC FOOT

APPENDIX II

JET ENGINE EXHAUST SIMILITUDE

Several different approaches were examined before establishing the scaling parameter employed in these studies. Details of the approach selected are presented below:

Nomenclature:

Full-Scale Vehicle: Subscript F Model: Subscript m

A_j = area of jet exit

K_T = thrust coefficient = $\frac{T}{\rho n^2 d^4}$

T = rotor thrust

V_j = jet velocity

V_o = ambient velocity

d = rotor diameter

n = rotor rps

t = temperature

ρ_j = density of jet exhaust

ρ_o = density of ambient air

Values Employed:

Full Scale:

A_j = 203 sq in.

V_j = 266 fps

d = 44 ft

t = ambient 90°F = 550°R
jet exhaust at exit = 1000°R
jet exhaust at tail = 660°R

Model:

$$A_j = 0.143 \text{ sq in.}$$

$$d = 14 \text{ in.}$$

$$\rho_j = \rho_o = 62.4 \text{ lb per cu ft}$$

Details of Approach:

$$\text{Keep the ratio } \left[\frac{\text{Total Momentum of Jet Exhaust}}{\text{Thrust of Tail Rotor}} = \text{Constant} \right]$$

for the model and full-scale condition:

$$\left[\frac{(\rho AV^2)_{\text{jet}}}{T} \right]_m = \left[\frac{(\rho AV^2)_{\text{jet}}}{T} \right]_F \quad (1)$$

In general, $T = K_T \rho d^4 n^2$,

$$\left[\frac{(\rho AV^2)_{\text{jet}}}{K_T \rho d^4 n^2} \right]_m = \left[\frac{(\rho AV^2)_{\text{jet}}}{K_T \rho d^4 n^2} \right]_F \quad (2)$$

Assume that K_T of the model tail rotor is equal to the K_T of the full-scale tail rotor,

$$\left[\frac{V_{j_m}}{V_{j_F}} \right]^2 = \frac{A_F}{A_m} \times \left[\frac{d_m}{d_F} \right]^4 \times \left[\frac{n_m}{n_F} \right]^2 \times \frac{[\rho_j / \rho_{\text{amb}}]_F}{[\rho_j / \rho_{\text{amb}}]_m} \quad (3)$$

The area ratios and diameter ratios are controlled by geometric scaling, which is 37.1:1.

The n ratio is established by:

- (1) Main-rotor to tail-rotor gearing ratios the same in the model as in full scale.
- (2) A full-scale main-rotor tip speed of 800 fps.
- (3) A model-rotor n of 8 rps

$$\frac{n_m}{n_F} = \frac{8 \text{ rps}}{\frac{800 \text{ fps}}{22 \text{ ft} \times 2\pi}} = \frac{8}{5.79}$$

Thus substituting in (3) with $\left[\frac{\rho_j}{\rho_{amb}}\right]_m = 1$,

$$\left[\frac{V_{j_m}}{V_{j_F}}\right]^2 = (37.7)^2 \left[\frac{1}{37.7}\right]^4 \times \left[\frac{8}{5.79}\right]^2 \times \left[\frac{\rho_j}{\rho_{amb}}\right]_F$$

$$\left[\frac{V_{j_m}}{266}\right]^2 = \left[\frac{1}{37.7}\right]^2 \times \left[\frac{8}{5.79}\right]^2 \times \left[\frac{\rho_j}{\rho_{amb}}\right]_F$$

$$V_{j_m} = \left[\frac{266 \times 8}{37.7 \times 5.79}\right] \times \left[\frac{\rho_j}{\rho_{amb}}\right]_F = 9.75 \left[\frac{\rho_j}{\rho_{amb}}\right]_F^{1/2} \text{ fps} \quad (4)$$

If the exhaust density were the same as the ambient density,

$$\left[\frac{\rho_j}{\rho_{amb}}\right]_F = 1; \text{ then substituting in (4)}$$

$$V_m = 9.75 \text{ fps}$$

but the average exit temperature from the nozzle (hot exhaust mixed with cold ejector-nozzle air) is of the order of $t = 1000^\circ\text{R}$.

Therefore, assuming a 90°F day,

$$\left[\frac{\rho_{jet}}{\rho_{amb}}\right]_F = \frac{t_{amb}}{t_{jet}} = \frac{550^\circ\text{R}}{1000^\circ\text{R}} = 0.55$$

and substituting in (4)

$$V_m = 9.75 \sqrt{0.55} = 7.2 \text{ fps}$$

This is the value employed in these studies.
